# Multi-city analysis

Time series analysis on environmental stressors often involves data from multiple cities

The reason: health effects usually change depending on **city-specific modifiers**, such as:

- climatic factors
- demographic factors
- socio-economic characteristics
- prevalence of air conditioning

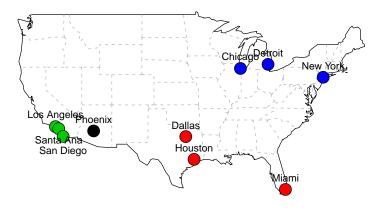

(日)、

## An example

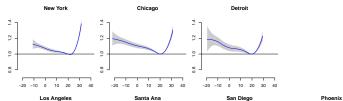

<ロト <回ト < 注ト < 注ト

#### 10 biggest NMMAPS cities

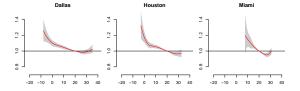

## Temperature and mortality

Ņ Q 0.8 æ æ -20 -10 -20 -10 -20 -10 -20 -10 30 40

## Multi-city analysis

The analytical framework is based on a **two-stage hierarchical design**:

- A first-stage time series regression model to estimate the exposure-response while controlling for potential confounders in each city
- A second-stage meta-analytical model to obtain a pooled estimate and investigate heterogeneity across cities

However, DLNMs hardly fit into this modelling approach

## Simple approaches of pooling

Traditional meta-analytic techniques only works for pooling estimates of a **single parameter** 

Adopting less sophisticated approaches, this can be achieved by:

- Restricting: seasonal analysis assuming a linear relationship
- Simplifying: linear-threshold parameterization
- Averaging over a predetermined lag period
- **Summarizing**: computing RR for specific absolute or relative temperatures

## Limitations

A D F A B F A B F A B F

These approaches, if generally appropriate, may not be suitable for investigating detailed associations. In particular:

- risk of **biases** due to wrong assumptions, or **limited info** on the true non-linear/delayed relationship
- **unbalance** between fairly complex first-stage models, compared to relatively simple second-stage meta-analytic procedures

What if we could **retain complexity** from the first-stage model, allowing the synthesis of more complex summary measures?

## Multivariate meta-analysis

Traditionally, an extension of traditional meta-analysis to combine estimates of **multiple outcomes** from RCT

MV-meta may also be applied to combine the estimates of **multi-parameter associations** from different studies

In this case, the estimated coefficients  $\hat{\theta}_i$  of the function  $s(x_t, \theta_i)$ , used in the first stage model to describe the association in each of the i = 1, ..., m cities

# Algebraic definition - I

Given the estimated  $\hat{\theta}_i$  and associated (co)variance matrix  $S_i$ : Within-study model

$$\hat{oldsymbol{ heta}}_i \sim {\sf N}_k(oldsymbol{ heta}_i\,,\,{f S}_i)$$

Between-study model

$$oldsymbol{ heta}_i \sim {\sf N}_k(oldsymbol{ heta}\,,\,oldsymbol{\Psi})$$

with  $\Psi$  as the between-study (co)variance matrix

## Algebraic definition - II

Marginally:

Multivariate meta-analysis

$$\hat{oldsymbol{ heta}}_i \sim {\sf N}_k(oldsymbol{ heta}\,,\,{f S}_i+oldsymbol{\Psi})$$

#### Multivariate meta-regression

$$\hat{oldsymbol{ heta}}_i \sim {\sf N}_k({\sf X}_ioldsymbol{eta}\,,\,{\sf S}_i+oldsymbol{\Psi})$$

with  $\mathbf{X}_i$  as a design matrix obtained by city-level predictors  $\mathbf{x}_i = [x_{1i}, x_{2i}, \dots, x_{pi}]^T$ 

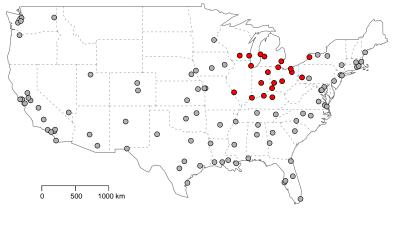

heta (or eta) and components of  $\Psi$  need to be estimated

## An application

• • • • • • • • • •

20 NMMAPS cities in the Industrial Mid-West region

## Two-stage analysis

Investigating the association between temperature and mortality

First-stage time series regression model with a **quadratic B-spline**, with:

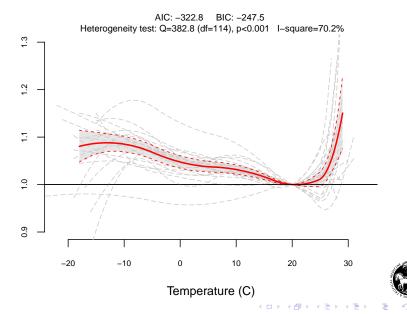

- Temperature averaged over lag 0-3
- 6 df
- 4 internal knots and 2 boundary knots placed at the same temperatures
- controlled for seasonality and day of the week

Then a second-stage multivariate meta-analysis and meta-regression

### Pooled relationship

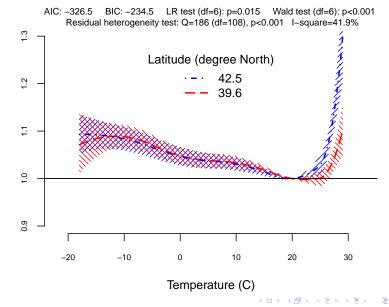

RR

## Best linear unbiased prediction

### Multivariate meta-regression

RR

## **DLNMs:** a reminder

They are specified through a **cross-basis**, a tensor product between the basis matrices **Z** and **C** for predictor and lag, with dimensions  $v_x$  and  $v_\ell$ , giving:

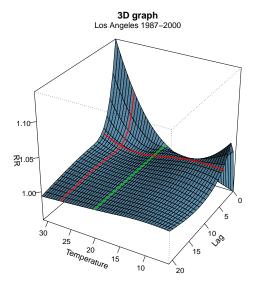

$$s(\mathbf{x}_t; \boldsymbol{\theta}) = \sum_{j=1}^{\mathbf{v}_x} \sum_{k=1}^{\mathbf{v}_\ell} \mathbf{r}_{tj}^{\mathsf{T}} \mathbf{c}_{\cdot k} \theta_{jk} = \mathbf{w}_{t\cdot}^{\mathsf{T}} \boldsymbol{\theta}$$
(1)

The cross-basis matrix **W** has dimension  $v_x \times v_\ell$ : for complex models, this **dimensionality is not compatible** with multivariate meta-analysis

# **Bi-dimensional relationship**

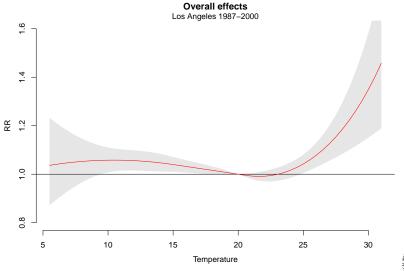

## Summary - II

イロト イロト イヨト イヨト ニヨート

# Reducing DLNMs - I

For a fitted DLNM with estimated parameters  $\hat{\theta}$ , summaries of the fit may be re-expressed in terms of reduced set of parameters  $\hat{\eta}$  of original one-dimensional bases **Z** or **C**.

These reduced parameters are computed through a **transformation matrix M**, by:

 $\hat{\boldsymbol{\eta}} = \boldsymbol{\mathsf{M}}\hat{\boldsymbol{ heta}}$  $\mathrm{V}(\hat{\boldsymbol{\eta}}) = \boldsymbol{\mathsf{M}}\mathrm{V}(\hat{\boldsymbol{ heta}})\boldsymbol{\mathsf{M}}^{\mathsf{T}}$ 

# Reducing DLNMs - II

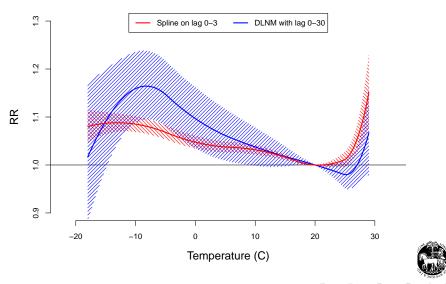

The computation of the matrix  ${\bf M}$  is dependent on the type of summary:

$$\mathbf{M} = \begin{cases} \mathbf{I}_{(v_{\ell})} \otimes \mathbf{z}_{[x_0]}^{\mathsf{T}} & \text{for predictor-specific effects at } x_0 \\ \mathbf{c}_{[\ell_0]}^{\mathsf{T}} \otimes \mathbf{I}_{(v_x)} & \text{for lag-specific effects at } \ell_0 \\ \mathbf{1}_{(L+1)}^{\mathsf{T}} \mathbf{C} \otimes \mathbf{I}_{(v_x)} & \text{for overall effects,} \end{cases}$$

Overall effects are computed as  $\mathbf{Z}\hat{\eta}$ , predictor-specific effects as  $\mathbf{C}\hat{\eta}$ , with a reduced dimensions  $v_x$  and  $v_\ell$ , respectively, more compatible with MV-meta models

## Comparison

## **DLNMs and MV-meta**

#### **Distributed lag non-linear models** and **multivariate meta-analysis** represent useful statistical tools for time series analysis of environmental factors

The methodologies are implemented in the two R packages dlnm and mvmeta, both available on CRAN  $\,$ 

Methodologies potentially applicable beyond time-series analysis
